X-884 US PATENT

REMARKS

DECLARATION

The Examiner stated in the Office Action:

The oath or declaration is defective because: It does not identify the city and either state or foreign country of residence of each inventor. The residence information may be provided on either an application data sheet or supplemental oath or declaration.

Applicant submitted the Declaration in compliance with 37 CFR 1.63 at the time of filing the application on October 30, 2001. Further, Applicant also submitted at the time of filing an Application Data Sheet with the above requested information. Applicant has attached a copy of both the Declaration and the Application Data Sheet as filed. Therefore, Applicant believes the Declaration in this application is not defective and complies with all Patent Office rules.

X-884 US PATENT

RESTRICTION REQUIREMENT

The Office Action stated that "Claims 1-19 are directed towards various and different embodiments of circuit structures that have varying methods of measuring signal skew because of the different circuit embodiments." The Office Action further states that Applicant is required under 35 U.S.C. 121 to elect a single disclosed species for prosecution on the merits to which the claims shall be restricted.

In full response to the Office Action, Applicant provisionally elects to prosecute Species I, including Claims 1-9, with traverse. Applicant hereby cancels Species II, Claims 10-19, but reserves the right to prosecute Species II (Claims 10-19) in a subsequent divisional application.

Respectfully submitted,

Justin Liu

Attorney for Applicant

METHODS AND CIRCUITS FOR MEASURING CLOCK SKEW ON PROGRAMMABLE LOGIC DEVICES

JUN 3 2004
TECH CENTER 2800

Siuki Chan

FIELD OF THE INVENTION

[0001] This invention relates generally to methods and circuit configurations for measuring signal skew in programmable logic devices.

Programmable logic devices (PLDs) are a well-

BACKGROUND

[0002]

known type of digital integrated circuit that may be programmed by a user (e.g., a circuit designer) to perform specified logic functions. One type of PLD, the fieldprogrammable gate array (FPGA), typically includes an array of configurable logic blocks (CLBs) that are programmably interconnected to each other and to programmable input/output blocks (IOBs). This collection of configurable logic is personalized by loading configuration data into internal configuration memory cells that define how the CLBs, interconnections, and IOBs are configured. For a detailed discussion of an exemplary FPGA, see U.S. Patent No. 6,144,220 entitled "FPGA Architecture Using Multiplexers that Incorporate a Logic Gate," by Steven P. Young, which is incorporated herein by reference. Figure 1 (Prior Art) depicts a conventional FPGA [0003] 100, examples of which include the Spartan™ and Virtex™ FPGAs available from Xilinx, Inc., of San Jose, California. FPGA 100 includes an array of programmably interconnected CLBs 105. FPGA 100 additionally includes a clock distribution network 110 that can be connected to internal

or external clock sources via a global clock buffer BUFG. Many other FPGA resources are omitted from Figure 1 for brevity.

Manufacturers of PLDs, including FPGAs, would [0004] like to guarantee the highest speed performance possible without their devices failing to meet timing specifications. PLD designers therefore measure circuit timing as accurately as possible to minimize the guard bands required to ensure correct device performance. U.S. Patent No. 6,144,262 entitled "Circuit for Measuring Signal Delays of Asynchronous Register Inputs," by Christopher Kingsley describes circuits and methods of measuring circuit timing in programmable logic devices, and is incorporated herein by reference. U.S. Patent No. 5,795,068 entitled "Method and Apparatus for Measuring Localized Temperatures and Voltages on Integrated Circuits," by Robert O. Conn describes ring oscillator configurations on FPGAs, and is also incorporated herein by reference.

clock distribution network 110 includes a source spine 110S that conveys clock signals to a source node 112 in the interior of FPGA 100. From there, a horizontal spine 110H conveys clock signals to a number of vertical clock spines 110V. Finally, a number of clock destination branches 110D extend to each CLB 105. Clock distribution network 110 can be programmably connected to any of CLBs 105 via programmable interconnect points. The above-cited Young patent describes exemplary programming technologies.

[0006] Clock distribution network 110 typically includes clock buffers 115 placed and sized to minimize clock skew, where skew is defined as the difference in path delays from clock input GCLK to each of CLBs 105 and any other clock

loads, such as embedded blocks of memory and IOBs. Many different buffer and conductor configurations are possible, the selected implementation depending upon design requirements.

[0007] High-performance clock distribution networks, such as network 110, are designed to minimized clock skew. The delays inherent in network 110 are typically short relative to the delays associated with other FPGA resources. The short skew is beneficial from the standpoint of performance, but renders difficult the task of accurately determining clock skew because conventional test circuitry normally introduces more skew than the clock distribution network. There is therefore a need for a more accurate means of measuring skew on programmable logic devices.

SUMMARY

[0008] The present invention is directed to a method for accurately measuring the skew of clock distribution networks on programmable logic devices. Individual clock distribution networks are modeled using a sequence of delay-element configurations formed on the device using configurable logic. Each delay element includes a portion of the clock network for which skew is of interest, and consequently exhibits a delay that depends, in part, on the skew imposed by the portion of interest. The delay through each delay element is measured by incorporating the delay elements into ring oscillators and measuring the resulting period.

[0009] The various delay-element configurations are modeled mathematically as the sum of a series of delays. The delay-element configurations are designed so their

respective equations can be combined to solve for the delay contribution, or skew, of the portion of the clock network for which skew is to be measured. The delay associated with the portion of interest can then be combined with skew measurements for other portions of the clock network to more completely describe the network.

[0010] The claims, and not this summary, define the scope of the invention.

BRIEF DESCRIPTION OF THE FIGURES

[0011] Figure 1 (Prior Art) depicts a conventional FPGA 100.

[0012] Figure 2 depicts an FPGA oscillator configuration 200.

[0013] Figure 3 depicts an FPGA oscillator configuration 300.

[0014] Figure 4 depicts an FPGA oscillator configuration 400.

[0015] Figure 5 depicts an FPGA oscillator configuration 500.

DETAILED DESCRIPTION

[0016] Figures 2-5 schematically depict FPGA configurations used in accordance with embodiments of the invention to accurately measure global clock skew for clock distribution network 110 of Figure 1. In the examples, the FPGA is a Virtex™ XCV1000 FPGA, available from Xilinx, Inc., which includes an array of 96 columns and 64 rows of CLBs, or a total of 6,144 CLBs. The number of CLBs and other FPGA resources shown in the figures is limited for brevity.

[0017] Figure 2 depicts an FPGA oscillator configuration 200 in which a CLB R2C24 (for row 2, column 24), a CLB R17C24, and a feedback circuit 205 are interconnected to form a ring oscillator. Circuit 205 and the associated connections 215 and 220 are made of available FPGA resources and connect to clock distribution network 110 via global clock buffer BUFG. The resources interconnected as shown using dashed and bold interconnect and clock lines form the ring oscillator.

[0018] The FPGA is programmed (i.e., configured) so the global clock buffer BUFG connects to the clock input terminal of CLB R2C24 via source spine 110S, horizontal clock spine 110H, a vertical clock spine 110V, and one of destination branches 110D. The synchronous output terminal of CLB R2C24 is programmably connected to an asynchronous input terminal of CLB R17C24 via some programmable interconnect resources R2->R17, so called because the routing connects row 2 to row 17. Finally, an output terminal of CLB R17C24 is programmably connected to the input terminal of global buffer BUFG via programmable interconnect resources 215 and 220 and circuit 205.

[0019] As oscillator configuration 200 oscillates, the oscillation period T_{200} provides a measure of the speed of the interconnected components. For example, if the average period T_{200} of configuration 200 is ten nanoseconds, then the average time required for positive- and negative-going signal transitions to traverse the ring of components is ten nanoseconds. The above-incorporated Kingsley patent describes some oscillators for use with the present invention.

[0020] The delay around the path of oscillator 200 is the sum of the delays associated with vertical spine 110V,

a one-column-long portion of a destination branch 110D, the clock-to-out (Clk->Out) delay of CLB R2C24, the interconnect delay of net R2->R17, and the combined delays K of the delays imposed by CLB R17C24, connections 215 and 220, circuit 205, buffer BUFG, and source spine 110S. The delay analysis can be simplified by assuming nearby CLBs exhibit identical clock-to-out (Clk->Out) delays. This is a reasonable assumption for identical components formed in close proximity.

[0021] Stated mathematically, the oscillation period T_{200} of oscillator configuration 200 is:

$$T_{200} = 30SK + C + Clk -> Out + DTB + K$$
 (1)

[0022] where SK is the skew imposed by spine 110V between adjacent clock destination branches 110D, C is the delay associated with a one-column-long portion of a branch 110D, Clk->Out is the clock-to-out delay of a CLB, DTB is the delay encountered by signals traveling from top-tobottom from row 2 to row 17 along net R2->R17, and K is the delay associated with that portion of oscillator configuration 200 depicted using dashed lines. described herein as having identical delays are defined using device programming software to establish identical or substantially identical routes, and therefore to impose identical or substantially identical delays. The process or forcing device programming software to select specific routing paths is well understood by those of skill in the art of defining circuit configurations for programmable logic devices.

[0023] The oscillation period T_{200} of configuration 200 is generally not, by itself, enough information to

determine the delay associated with any one of the components of the ring. The FPGA is therefore reconfigured to form one or more additional test structures.

Figure 3 depicts an FPGA configuration 300 in [0024] which CLB R17C24, CLB R32C24, global clock buffer BUFG, and the identical circuit 205 of Figure 2A are interconnected to form a second ring oscillator. CLB R17C24, circuit 205, clock buffer BUFG, and the dashed portion of clock distribution network 110 and interconnect resources 215 and 220 are identical to the like-identified structures of Figure 2; consequently, the sum of the combined delay contributions of those dashed elements, "K" in equation 1, is identical in oscillator configurations 200 and 300. The portions of the oscillators depicted as connected via solid lines in the figures can be considered delay elements for which the difference in signal propagation delays provides a measure of clock skew. Including the delay elements in ring oscillators allows for accurate measures of propagation delay through the delay elements.

[0025] The FPGA of Figure 3 is programmed so the clock input terminal of CLB R32C24 connects to the output terminal of global clock buffer BUFG via a one-column long portion of one of destination branches 110D, vertical spine 110V, horizontal spine 110H, and one of source spines 110S. The synchronous output terminal of CLB R32C24 is programmably connected to an input terminal of CLB R17C24 via some programmable interconnect resources R32->R17. Finally, as in configuration 200, an output terminal of CLB R17C24 is programmably connected to the input terminal of global buffer BUFG via programmable interconnect resources 215 and 220 and circuit 205. The dashed portions of

oscillator configurations 200 and 300 are identical, each imposing a delay K.

[0026] Stated mathematically, the oscillation period T_{300} of oscillator configuration 300 is:

$$T_{300} = C + Clk -> Out + DBT + K$$
 (2)

[0027] where C is the delay associated with a one-column-long portion of a branch 110D, Clk->Out is the clock-to-out delay of CLB R32C24, DBT is the delay encountered by signals traveling from bottom-to-top from row 32 to row 17 along net R32->R17, and K is the delay associated with that portion of oscillator configuration 300 depicted using dashed lines, including the delay induced by CLB R17C24.

[0028] Comparing periods T_{200} and T_{300} of respective configurations 200 and 300 provides a measure of the skew SK between adjacent destination branches. Subtracting equation 2 from equation 1 gives:

$$T_{200} - T_{300} = (30SK + C + Clk -> Out + DTB + K) - (C + Clk -> Out + DBT + K)$$

$$= 30SK + DTB - DBT$$
(3)

Solving for skew SK provides:

$$SK = (T_{200} - T_{300} + DBT - DTB)/30$$
 (4)

[0029] Different programmable logic devices route differently. For a given PLD, the values of delays DBT and DTB may be close enough to assume they cancel one another. This assumption reduces equation 4 to:

$$SK = (T_{200} - T_{300})/30 \tag{5}$$

[0030] Thus, if DTB and DBT are equal, periods T_{200} and T_{250} are measures of skew SK. Of course, skew SK can also be used to find the skew between non-adjacent destination branches 110D; for example, the skew between destination branches separated by a row of CLBs would be 2SK.

[0031] It may be difficult or impossible to route some PLDs such that the top-to-bottom connections (e.g., net R2->R17) provide the same delays as the bottom-to-top connections (e.g., net R32->R17). In such cases, equation 4 cannot be simplified to equation 5.

Figures 4 and 5 depict respective oscillator [0032] configurations 400 and 500, the periods of which provide additional data for finding the skew SK between adjacent destination branches 110D in the event of unequal top-tobottom and bottom-to-top delays DTB and DBT. As with the preceding figures, the dashed and bold lines indicate which components form the oscillators. The dashed lines 405, CLB R48C24, and feedback circuit 410 are identical circuit configurations in both Figures 4 and 5, and their equivalent delay contributions are symbolized by a constant The ring oscillators in each of Figures 4 and 5 can be configured as described in the above-incorporated Kingsley In the depicted embodiment, CLB R48C24 is configured to be an asynchronous inverter, though different asynchronous or synchronous configurations might also be used. Circuit 410 and the associated connections 405 are made of available FPGA resources and connect to clock distribution network 110 via global clock buffer BUFG.

[0033] The FPGA of Figures 2 through 4 is configured such that net R33->R48 of configuration 400 (Figure 4) is

identical to net R2->R17 of oscillator configuration 200 (Figure 2) so the delays DTB associated with these nets are identical, or nearly so. Likewise, net R63->R48 (Figure 5) is identical to net R32->R17 (Figure 3) so the delays DBT associated with these nets are identical.

[0034] Using the same method described above for determining the periods associated with oscillator configurations 200 and 300, the respective periods T_{400} and T_{500} of oscillator configurations 400 and 500 are:

$$T_{400} = C + Clk -> Out + DTB + M$$
 (6) and

$$T_{500} = 30SK + C + Clk -> Out + DBT + M$$
 (7)

Subtracting equation 6 from equation 7 gives:

$$T_{500} - T_{400} = (30SK + C + Clk - > Out + DBT + M) - (C + Clk - > Out + DTB + M)$$

$$= 30SK + DBT - DTB$$
(8)

Solving for DBT - DTB gives:

$$DBT - DTB = T_{500} - T_{400} - 30SK$$
 (9)

[0035] Oscillator configurations 400 and 500 thus provide a measure of the difference in delays between bottom-to-top and top-to-bottom programmable interconnections between rows of CLBs.

[0036] The result of equation 9, DBT-DTB, can be used to solve for skew SK using equation 4 as follows:

$$SK = (T_{200} - T_{300} + T_{500} - T_{400} - 30SK)/30$$
 (10)

or

$$SK = (T_{200} - T_{300} + T_{500} - T_{400})/60$$
 (11)

[0037] Thus, the four oscillator configurations depicted in Figures 2-5 collectively provide enough information to determine the skew SK between adjacent destination branches 110D.

[0038] Skew measurements between vertical clock spines 110V may also be of interest, and can be combined with the above-described skew measurements to give a comprehensive skew analysis for an entire device. Patent Application Serial No. ______ entitled "METHODS AND CIRCUITS FOR MEASURING CLOCK SKEW ON PROGRAMMABLE LOGIC DEVICES," by Siuki Chan, filed herewith [docket number X-884], describes methods of measuring skew between vertical clock spines and is incorporated herein by reference.

[0039] FPGA components are connected in various ways: some components are directly connected, others are connected via intermediate components, such as buffers, and still others are programmably connectable, which is to say they can be programmably connected via programmable interconnect resources. In each instance, components are connected to establish some desired electrical communication between two or more circuit nodes, or terminals. Such communication may typically be accomplished using a number of circuit configurations, as will be understood by those of skill in the art.

[0040] While the present invention has been described in connection with specific embodiments, variations of these embodiments will be obvious to those of ordinary skill in the art. For example, multiple embodiments of the above-described oscillator configurations can be used

simultaneously on devices that include more than one signal tree for which skew measurements are of interest.

Moreover, above-described skew measurements can be done in any order, and other columns of CLBs (e.g., column 25 of Figures 2-5) could be used to perform skew measurements.

Therefore, the spirit and scope of the appended claims should not be limited to the foregoing description.

CLAIMS

What is claimed is:

1. A method of measuring signal skew of a signal tree on a programmable logic device, the device including a signal tree having a source node connected to first, second, and third destination branches, first, second, and third logic blocks programmably connectable to the respective first, second, and third destination branches, each of the logic blocks having an input terminal and an output terminal, the method comprising:

- a. instantiating a first delay element on the device using a first programming sequence that includes:
 - i. connecting the first destination branch to the input terminal of the first logic block;
 and
 - ii. connecting the output terminal of the first logic block to the input terminal of the second logic block; and
- b. instantiating a second delay element on the device using a second programming sequence that includes:
 - i. connecting the third destination branch to the input terminal of the third logic block;
 and
 - ii. connecting the output terminal of the third logic block to the input terminal of the second logic block.

The method of claim 1, wherein the signal tree is a clock tree.

- 3. The method of claim 1, wherein the input terminal of the second logic block is an asynchronous input terminal.
- 4. The method of claim 1, wherein the first, second, and third logic blocks are arranged on the device in a column.
- 5. The method of claim 4, wherein the second logic block is physically between the first and second logic blocks.
- 6. The method of claim 1, wherein the source node is further connected to fourth, fifth, and sixth destination branches and the programmable logic device further includes fourth, fifth, and sixth logic blocks programmably connectable to the respective fourth, fifth, and sixth destination branches, each of the logic blocks having an input terminal and an output terminal, the method further comprising:
 - c. instantiating a third delay element on the device using a third programming sequence that includes:
 - i. connecting the fourth destination branch to the input terminal of the fourth logic block; and
 - ii. connecting the output terminal of the fourth logic block to the input terminal of the fifth logic block; and

d. instantiating a fourth delay element on the device using a fourth programming sequence that includes:

- i. connecting the sixth destination branch to the input terminal of the sixth logic block;
 and
- ii. connecting the output terminal of the sixth logic block to the input terminal of the fifth logic block.
- 7. The method of claim 6, wherein connecting the output terminal of the first logic block to the input terminal of the second logic block establishes a first net, connecting the output terminal of the second logic block to the input terminal of the second logic block establishes a second net, connecting the output terminal of the fourth logic block to the input terminal of the fifth logic block establishes a third net, and connecting the output terminal of the sixth logic block to the input terminal of the fifth logic block establishes a fourth net, the method further comprising defining the first and third nets to be identical and defining the second and fourth nets to be identical.
- 8. The method of claim 1, further comprising configuring the device to include the first and second delay elements in respective first and second oscillators.
- 9. The method of claim 8, further comprising comparing the periods of the first and second oscillators.

- 10. A method comprising:
 - a. programming a programmable logic device to include a first delay element, the first delay element including:
 - i. a first destination branch connected to a clock source node;
 - ii. a first logic block having a first input terminal and a first output terminal, wherein the first input terminal is programmably connected to the first destination branch;
 - iii. a second logic block having a second input terminal and a second output terminal, wherein the second input terminal is programmably connected to the first output terminal; and
 - b. programming the programmable logic device to include a second delay element, the second delay element comprising:
 - i. a second destination branch connected to the clock source node; and
 - ii. a third logic block having a third input terminal and a third output terminal, wherein the third input terminal is programmably connected to the second destination branch and the third output terminal is programmably connected to the second input terminal.
- 11. The method of claim 10, wherein the first and second delay elements are portions of respective first and second oscillators.

12. The method of claim 11, wherein the first oscillator includes a first net connected between the second output terminal and the clock source node, wherein the second oscillator includes a second net connected between the second output terminal and the clock source node, and wherein the first and second nets are identical.

- 13. The method of claim 10, wherein the first and second destination branches are parallel, and wherein the second logic block is disposed physically between the first and second destination branches.
- 14. The method of claim 13, further comprising a third destination branch parallel to the first and second destination branches, wherein the second logic block is programmably connectable to the third destination branch.
- 15. A method of calculating a first signal propagation delay along a portion of a signal distribution network on a programmable logic device, the method comprising:
 - d. instantiating a first delay element on the device using a first programming sequence, wherein the first delay element includes the portion of the signal distribution network;
 - e. determining a second signal propagation delay through the first delay element;
 - f. instantiating a second delay element on the device using a second programming sequence,

- wherein the second delay element includes the portion of the signal distribution network; and
- g. determining a third signal propagation delay through the second delay element.
- 16. The method of claim 15, wherein the first signal propagation delay is proportional to the difference between the second and third signal propagation delays.
- 17. The method of claim 15, wherein instantiating the first delay element includes instantiating a first ring oscillator that includes the first delay element, and wherein instantiating the second delay element includes instantiating a second ring oscillator that includes the second delay element.
- 18. The method of claim 17, wherein determining the second and third signal propagation delays includes measuring the oscillation period of the respective first and second oscillators.

ABSTRACT OF THE DISCLOSURE

Described are methods for accurately measuring the skew of clock distribution networks on programmable logic devices. Clock distribution networks are modeled using a sequence of oscillators formed on the device using configurable logic. Each oscillator includes a portion of the network, and consequently oscillates at a frequency that depends on the signal propagation delay associated with the included portion of the network. The various oscillator configurations are defined mathematically as the sum of a series of delays, with the period of each oscillator representing the sum. The respective equations of the oscillators are combined to solve for the delay contribution of the included portion of the clock network. The delay associated with the included portion of the clock network can be combined with similar measurements for other portions of the clock network to more completely describe the network.
